Abstract:

“Rusty pipe syndrome” is a condition in a primiparous woman who presents with bilateral bloody nipple discharge in the early postpartum period. Its prevalence is low and can occur due to physiological condition that arises primarily in primiparous women with increased alveolar and ductal vascularization associated with the onset of lactation. Here, we report a case of a 29-year-old primiparous who presented with bilateral painless bloody nipple discharge after delivery. Her breast examination showed no signs of infection or structural changes with no symptoms other than bloody nipple discharge. Eight days after the onset of lactation, the bloody nipple discharge ceased and patient advised to continue lactation.

I. Introduction:

Discharge of blood-stained maternal milk after delivery is a rare phenomenon, with an estimated prevalence rate of 0.1% [1]. Bloody nipple discharge during lactation occurs as a result of several factors such as cracked nipples, mastitis, trauma, or intraductal papilloma [2,3]. However, a rare physiological condition, known as “rusty-pipe syndrome”, can cause painless bloody nipple discharge in pregnant and post-partum women [3,4]. Rusty pipe syndrome is a breastfeeding condition in which the color of the breast milk looks pink, orange, brown, or rust-colored, similar to dirty water coming out of an old rusty pipe, and hence, the name of the syndrome. The rusty-colored milk usually appears during the first few days of breastfeeding. In most cases, the syndrome is spontaneously cured within 3 to 7 days after the onset of lactation [4]. In other cases, this condition persists for the first few weeks of lactation, and is eventually resolved spontaneously [5].

II. Case Report:

Mrs. X, a 29-year-old primipara delivered a male baby through LSCS at 38 weeks and 2 days of gestational age due to non-progress of labour with birth weight of 3575 grams at Matru Seva Sangh, Mahal, Nagpur. In the first hours after birth, the new mother experienced painless bilateral brownish nipple discharge and inverted nipples. She was attended by a staff nurse in the ward for inverted nipple using the syringe technique. Her breast examination showed no signs of inflammation, engorgement, tenderness, or palpable masses. The nipples were inverted and showed no cracks, ulcers, or fissures. Examination of the newborn’s mouth revealed no natal teeth. She noticed that the nipple discharge color changed from dark brown in the morning to light brown in the afternoon. She was advised to express her breast every 2 to 3 hours to avoid breast engorgement. The bloody discharge resolved spontaneously 8 days after delivery with the onset of normal milk production, after which, the bloody discharge did not recur.

Informed consent:

Informed consent was obtained from the patient for publication of this case report and accompanying images.

III. Discussion:

“Rusty pipe syndrome” is a rare benign and self-limiting physiological condition that should be included in the differential diagnosis in women who present with painless bloody nipple discharge during gestation and lactation [2]. Rusty pipe syndrome occurs due to elevated vascularization of rapidly developing alveoli that have a delicate network of capillaries. These capillaries are easily traumatized, which results in bleeding from the nipples [2,6]. This condition commonly occurs in primiparous women who present with bilateral painless nipple discharge after delivery, with no signs of inflammation in the breast and no previous history of trauma [2]. The syndrome may begin at the time of birth, during early lactation, or during pregnancy. The onset of the syndrome may involve unilateral breast [3]. It is usually associated with nipple stretching exercises, such as Hoffman’s procedure, which is often recommended for flat or inverted nipples [3,4]. However, in our case, the syringe technique was employed to treat the inverted nipple based on the guidelines of “session 12: breast and nipple conditions” by the World Health Organization and United Nations Children’s Fund, and Baby-Friendly Hospital

Initiative, 2009 [7]. In addition, physical examination did not reveal any skin changes, nipple cracks or fissures, breast engorgement or lump, and fever [2]. Initial diagnosis of “rusty pipe syndrome” is based on medical history and routine physical examination, followed by specialized investigations, if necessary, including cytological analysis of the bloody discharge, to exclude the presence of malignant cells, and breast ultrasound, which could help rule out other pathological conditions [2,3]. Bloody nipple discharge during lactation can be related to the breastfeeding technique that causes cracked nipples, mastitis, or trauma, and its occurrence can be attributed to various pathological causes such as intraductal papilloma [2,3]. Intraductal papilloma is a benign tumor found within the breast ducts, in which abnormal proliferation of ductal epithelial cells causes tumor growth. A solitary intraductal papilloma is usually found located centrally posterior to the nipple that affects the central duct. Patients often present with spontaneous bloody or clear nipple discharge. An intraductal papilloma may be occasionally palpable. The breast ultrasound usually reveals a mass near the nipple. Tissue sampling, in addition to imaging, is necessary for the diagnosis of intraductal papilloma. Treatment of intraductal papilloma involves surgical excision and complete removal of the tumor [8].

Persistent bloody nipple discharge immediately after the postpartum period should be evaluated using diagnostic imaging. Ultrasonography is recommended as the initial diagnostic imaging modality in a breastfeeding woman. If the ultrasonography reveals suspicious findings or is discordant with the clinical examination, additional imaging using mammography or digital breast tomosynthesis (DBT or “three-dimensional mammography”) may be indicated. This is related to the fact that mammography or DBT can visualize architectural distortion and/or calcifications that cannot be seen on ultrasonography, as well as delineate the extent of the disease in case of malignancy [5].

In summary, “rusty pipe syndrome” during pregnancy and lactation is an uncommon and harmless condition, but can be alarming to the mother, caregivers, and medical personnel [9]. It is a self-limiting condition and is usually resolved within three to seven days after onset of lactation [4]. In our case, the patient is a healthy primiparous woman who exhibits a typical “rusty pipe syndrome,” with spontaneous and self-resolving bloody nipple discharge. In “rusty pipe syndrome” cases, if the infant tolerates the milk, then breastfeeding can be continued and encouraged to strengthen exclusive breastfeeding practice for 6 months [6,9]. The discharge should be further examined if the bleeding persists for more than one week to exclude papilloma [6].
